ABSTRACT

Little is known about the relationship between diet and metabolic health in Latino children, a population at increased risk for diabetes. The present study evaluates diet composition and the metabolic syndrome in a cross-sectional sample of 109 overweight Latino children aged 10 to 17 years with a family history of type 2 diabetes. Dietary intake was assessed by two 24-hour recalls. Associations between nutrients and features of the metabolic syndrome were examined using multiple linear regression and analysis of covariance. Log cholesterol intake was positively associated with log systolic blood pressure (β=0.034, P=0.017) and log soluble dietary fiber intake was inversely associated with log waist circumference (β=−0.069, P=0.036). Log soluble fiber intake was significantly higher in participants with 0 features compared to those with 3+ features of the metabolic syndrome (P=0.046), which translates to 5.2 g vs 4.1 g soluble fiber daily. No other significant associations were found between dietary variables and either the individual features of the metabolic syndrome or the clustering of metabolic syndrome components. Increases in soluble fiber through the daily consumption of fruits, vegetables, and beans may improve metabolic health in Latino children.

The Third National Health and Nutrition Examination Survey data showed that 29% of overweight adolescents aged 12 to 19 years and 4% of all US adolescents have the metabolic syndrome, a clustering of risk factors for diabetes and cardiovascular disease (1). The metabolic syndrome is most common in Mexican-American adolescents (5.6%), followed by whites (4.8%) and African Americans (2.0%) (1), making the examination of risk factors particularly warranted in Latino populations.

Studies have identified high intake of total fat and added sugar and low intake of fiber as risk factors for the metabolic syndrome in adults (2,3), but research in youth is limited. In a study of 154 white girls, sweetened beverages were the only dietary component related to the metabolic syndrome (4). A study of 12,441 Korean youth showed that those who ate a more “Western” diet had higher waist circumferences, although they were not more likely to have the metabolic syndrome (5). The present study investigates the associations between dietary intake and prevalence of risk factors for the metabolic syndrome in a sample of overweight Latino children with a family history of diabetes.

METHODS

Subjects

Participants represent a subset of the University of Southern California Study of Latino Adolescents at Risk for Diabetes Project, a longitudinal cohort study aimed to track the incidence of type 2 diabetes in Latino children who were ages 8 to 13 years at baseline in 2001 through 2003. Detailed methods for the longitudinal study have been published previously (6-8). The present, cross-sectional study includes 113 participants for whom dietary and clinical data for the five features of the metabolic syndrome were collected in 2005 through 2006. None of the participants were diabetic. This study was approved by the university Institutional Review Board. Written E. E. Ventura, C. E. Byrd-Williams, and C. M. Toledo-Corral are research assistants and doctoral students, J. N. Davis is an assistant professor, L. A. Kelly is a research associate, K. E. Alexander is a research assistant, and C. J. Lane is a biostatistician, Department of Preventive Medicine; and W. Lee is a research assistant, Department of Biostatistics; all at the University of Southern California, Keck School of Medicine, Los Angeles. G. Q. Shaibi is a postdoctoral research fellow, College of Nursing and Healthcare Innovation, Arizona State University, Phoenix. M. J. Weigensberg is associate professor, Clinical Pediatrics, Keck School of Medicine, University of Southern California, and director, Pediatric Endocrinology, Los Angeles County and University of Southern California Medical Center, Los Angeles. M. I. Goran is professor of preventive medicine, physiology and biophysics, University of Southern California, Keck School of Medicine, Los Angeles; he is also director, USC Childhood Obesity Research Center (CORC), Los Angeles, CA.

informed consent was obtained from parents and youth assent from participants.

Protocol
Body mass index (BMI; calculated as kg/m²) and BMI percentiles for age were determined based upon established Centers for Disease Control and Prevention normative curves (9). Sitting blood pressure was measured in triplicate using the right arm after the participant rested for 5 minutes (10). Waist circumference was measured at the umbilicus and recorded to the nearest 0.1 cm. Body composition was measured by whole-body dual-energy x-ray absorptiometry. Tanner stage was assessed by a licensed pediatric health care provider (11). Fasting blood samples were measured for triglycerides and high-density lipoprotein (HDL) cholesterol. Impaired glucose tolerance was defined as a 2-hour postchallenge plasma glucose value of at least 140 and <200 mg/dL (≥7.77 and <11.1 mmol/L) (12).

Definition of the Metabolic Syndrome
The validity of the use of the metabolic syndrome as a clinical measure is still debated and no standard definition exists for children and adolescents. For the current analysis, the metabolic syndrome was categorized using a definition we have proposed previously (6), which applies pediatric cutoffs to the Adult Treatment Panel III definition (13). To classify as having the metabolic syndrome, participants had to have three or more of the following: abdominal obesity (waist circumference ≥90th percentile for age, sex, and Hispanic ethnicity from Third National Health and Nutrition Examination Survey data) (14), hypertriglyceridemia (triglycerides ≥90th percentile of age and sex) (15), low HDL cholesterol (HDL cholesterol ≤10th percentile for age and sex) (15), elevated blood pressure (systolic or diastolic blood pressure >90th percentile adjusted for height, age, and sex) (10), and impaired glucose tolerance, as described here.

Dietary Intake
Dietary intake was assessed with two 24-hour recalls from each participant using the multiple-pass technique, which has been validated against the doubly labeled water method in children (16). One recall was administered in person by a bilingual dietary technician with the use of three-dimensional food models, and the second recall was administered via an unscheduled phone call by the same technician in the following week. Nutrition data were analyzed using the Nutrition Data System for Research (version 5.0.35), a software program developed by the University of Minnesota, and all entries were checked for accuracy by a second technician. This study focuses on macronutrients and does not investigate micronutrients or dietary patterns. The Nutrition Data System program defines added sugars as sugars/syrups added to foods during preparation or processing, such as high fructose corn syrup, but not including naturally occurring sugars like lactose and fructose.

During the collection of the 24-hour recalls, when a participant’s intake seemed excessively low or high, the technician asked if he or she considered the day’s intake to be usual. When a participant indicated that the day’s intake was not usual, the recall was not included in the analysis. Of 113 participants, three were excluded from the sample because both days of intake were said to not be usual. Of the remaining 110 participants, 21 commented that 1 day of intake was not usual. This left 89 participants with two recalls and 21 with one recall.

There were no statistically significant differences in clinical characteristics, dietary characteristics, or metabolic syndrome status between participants with one vs two recalls. Subsequently, the dietary data were examined for plausibility of caloric intake by assessing the residuals of the linear regression of caloric intake and body weight. One participant was excluded due to a residual that was >3 standard deviations from the mean, leaving 109 participants in the sample.

Statistical Analyses
For the preliminary analyses, participants were dichotomized into those with and those without the metabolic syndrome. Independent t tests or Wilcoxon rank sum tests were used to compare clinical and dietary variables between the two groups, and a ë test was performed to compare sex distributions. Effect sizes of trends were calculated by (µΔ)/(SDpooled), where µΔ is the difference in the two means and SDpooled is the pooled standard deviation.

Relationships between nutrients and the separate features of the metabolic syndrome were assessed with simple Pearson correlations, and significant correlations were further explored with multiple linear regression. Variables that were not normally distributed were log-transformed for the multiple regression analyses. To examine differences in dietary intake across the number of features of the metabolic syndrome, analysis of covariance (ANCOVA) was used with a Tukey adjustment for multiple comparisons.

In the multiple regression and ANCOVA models, sex, age, Tanner stage, and total energy intake were added as covariates. In addition to energy intake, noncarbohydrate macronutrient intake (grams of protein and fat) was controlled for in the fiber models and nonfat macronutrient intake (grams of carbohydrate and protein) and body composition were controlled for in the dietary cholesterol models. Data were analyzed with SAS (version 9.1, 2003, SAS Institute, Cary, NC) and type 1 error was set at P<0.05.

RESULTS AND DISCUSSION
The most prevalent components of the metabolic syndrome were low HDL cholesterol (52%) and high waist circumference (48%), and the prevalence of the metabolic syndrome was 22%.

Clinical and dietary characteristics by metabolic syndrome status are shown in the Table. The metabolic syndrome was more prevalent in males than females (29% vs 13%; P=0.042). Participants with the metabolic syndrome were significantly younger (13.7 vs 14.5 years, P=0.040) and less sexually mature (Tanner stage 3.2 vs 3.8, P=0.032). Participants with the metabolic syndrome had a higher BMI (33.0 vs 30.7; P=0.010) and more fat
mass (33.9 vs 27.1 kg; *P*=0.004). There were no statistically significant differences in dietary intake between those with and those without the metabolic syndrome. However, there was a trend toward significance for those who did not have the metabolic syndrome to eat more grams of total fiber per 1,000 calories (*P*=0.096). This trend showed a small effect size of 0.3 (17).

There were significant inverse Pearson correlations between the three measures of dietary fiber (total, soluble, and insoluble) and waist circumference (*r*=−0.21 to −0.27, *P*<0.05). There was also a positive correlation between dietary cholesterol and systolic blood pressure (*r*=0.22, *P*=0.022). None of the other features of the metabolic syndrome were correlated with any of the dietary variables. Multiple linear regression confirmed that log dietary cholesterol was positively associated with log systolic blood pressure (β=0.034, *P*=0.017). This is equivalent to a 0.020 mm Hg increase in systolic blood pressure for a 1 SD increase in cholesterol intake (129.68 mg). Multiple regression models of fiber intake and waist circumference revealed a trend toward significance for an inverse association with total dietary fiber (β=−0.060, *P*=0.071), a nonsignificant association with insoluble fiber (β=−0.047, *P*=0.109), and a significant inverse association with soluble dietary fiber (β=−0.069, *P*=0.036).

In the soluble fiber model, each standard deviation increase in soluble fiber (1.91 g) equates to a 0.022-cm decrease in waist circumference. Although the coefficients for dietary cholesterol and soluble fiber are small, they are nonetheless significant, perhaps considering how many factors contribute to blood pressure and to waist circumference.

Using ANCOVA, dietary variables were examined across participants grouped by number of features of the metabolic syndrome. Log cholesterol intake did not differ between groups (*P*=0.105 for comparison between 0 and 3+ features). However, log soluble fiber intake was significantly higher in those with 0 features as compared to those with 3+ features after controlling for covariates (*P*=0.046). The untransformed values amount to a 1.1 g difference in soluble fiber intake between groups; those with 3+ features ate 5.2 g per day as compared to those with 0 features who ate 4.1 g per day (Figure). No significant differences were found in ANCOVA models examining the other dietary variables, listed in the Table (energy, protein, total fat, saturated fat, polyunsaturated fat, carbohydrate, added sugar, total dietary fiber, or insoluble fiber).

To our knowledge, this study is the first to show an association between soluble fiber and the metabolic syndrome in children. Results from studies in adults also link low fiber intake with the metabolic syndrome (18,19).
Studies in youth and young adults have found relationships between fiber intake and individual components of metabolic risk. Ludwig and colleagues (20) found that fiber consumption was a better predictor of fasting and 2-hour insulin levels and waist-to-hip ratio than total or saturated fat consumption in young adults. Steffen and colleagues (21) showed that increased dietary fiber from whole grains was associated with lower body mass and greater insulin sensitivity among adolescents. However, few studies isolate the effects of soluble fiber, which can decrease adiposity by delaying gastric emptying and promoting satiety (22,23).

Boys in the United States, aged 12 to 15 years, eat 15 g fiber per day, and girls of the same age eat 13 g per day, whereas the Adequate Intake reference values for boys and girls are 31 g and 26 g, respectively (24,25). Participants in the present study without the metabolic syndrome ate 14.8 g fiber per day and those with the metabolic syndrome ate 13.6 g. This equates to 8.2 g fiber per 1,000 calories, which is only 58% of the Institute of Medicine's recommendation of 14 g fiber per 1,000 calories (26).

Participants with zero features of the metabolic syndrome ate 27% more soluble fiber than those who had the metabolic syndrome. This represents a relatively small, yet substantial difference of only 1.1 g/day, or the equivalent of one apple or one serving of beans. The five most common sources of 1 g or more of soluble fiber consumed by this cohort were: whole fresh fruit (orange, apple, mango, and pear), beans (boiled and refried), potatoes (including french fries), bread products, and chocolate milk (carageenan stabilizers are added to chocolate milk and add 1.45 g soluble fiber per 8 fluid ounces). Considering that not all of these are considered healthful foods, the quantity and frequency of consumption as well as the combination of different sources of soluble fiber can be important.

There are several limitations that should be considered regarding this study. The small sample size limits statistical power and can hinder the ability to detect associations between diet and the metabolic syndrome. In addition, the cross-sectional nature of the study prevents conclusions about causality. There might be a cohort effect, as participants had been retained in the study for 3 to 6 years. Potential contributors to measurement error include the age of participants, the use of 24-hour recalls, the availability of only one recall for 21 subjects, and the focus on macronutrients as opposed to dietary patterns. Finally, overweight participants can be especially prone to underreporting dietary data (27).

The impact of measurement error would be to attenuate the observed relationships and to contribute to weak or null findings.

CONCLUSIONS

The only dietary variable that was associated with the overall metabolic syndrome in this cohort of overweight Hispanic children was soluble fiber. Dietary interventions aimed at increasing soluble fiber, by including one extra serving of fruit, vegetables, or legumes daily, could reduce central adiposity and improve metabolic health in Latino adolescents. Therefore, a targeted, positive message focusing on adding soluble fiber to the daily diet is suggested.
